## Beams in Buildings

Beams

Giacomo Boffi

[Introduction](#)

[General Principles](#)

[Beams in Buildings](#)

[Basic Stress Distributions](#)

[Analysis of Beams](#)

[Design of Beams](#)

The stresses in a beam depend on the bending moment value and on shape of the cross section.

- ▶ The bending moment depends on the value of the loading, on the span of the beam and on the support conditions.
- ▶ In general, the larger the section the lower the stresses, but also the shape and its orientation w/r to loading direction is important, in particular an increase of the depth leads to an important decrease of the maximum stresses.

## Basic Stress Distributions

Beams

Giacomo Boffi

[Introduction](#)

[General Principles](#)

[Beams in Buildings](#)

[Basic Stress Distributions](#)

[Analysis of Beams](#)

[Design of Beams](#)

At any cross section the resultant of the stresses must equal the shear force and the bending moment.

- ▶ The shear force, that acts in the direction of the depth of the section, is equilibrated by tangential stresses.
- ▶ The bending moment, that acts perpendicular to the cross section, is equilibrated by normal stresses.

Beams

Giacomo Boffi

Introduction

General Principles

Beams in Buildings

Basic Stress Distributions

Analysis of Beams

Design of Beams

- ▶ The moment cause the beam to bow, in our figure top fibers are shorted and bottom fibers are elongated.
- ▶ There are fibers whose length is not varied, these fibers cross the section on a line called the *neutral axis*.
- ▶ The amount of length variation depends linearly on the distance  $y$  from the neutral axis.
- ▶ The stresses, for a linear elastic material, depends on the amount of length variation (a.k.a. deformation) and are hence linearly varying, with positive and negative extremes on the borders of the cross section.

## Bending Stresses

Beams

Giacomo Boffi

Introduction

General Principles

Analysis of Beams

Bending Stresses

Lateral Buckling

Shear Stresses

Bearing Stresses

Torsion

Shear Center

Deflections

Principal Stresses

Design of Beams

The stresses are proportional from the distance  $y$  from the neutral axis, are proportional to the bending moment and are inversely proportional to a property of the dimensions and shape of the cross section, that we call moment of inertia and denote with the symbol  $J$ . (nb dimensional analysis)

$$\sigma = My/J$$

### Example

Simply supported beam,  $L = 8$  m,  $p = 60 \frac{\text{kN}}{\text{m}}$ ,  $M_{\max} = \frac{pL^2}{8} = 480$  kNm.  
For a rectangular section it is  $J = bd^3/12$  and  $y_{\max} = b/2$ .

The maximum stress is  $\sigma_{\max} = \frac{\frac{pL^2}{8} \times \frac{d}{2}}{bd^3/12}$  and with  $b = 0.3$  m,  $d = 0.6$  m it is  
 $\sigma_{\max} = 26\,666\,667 \frac{\text{N}}{\text{m}^2} = 26.67$  MPa

## Bending Stresses

Beams

Giacomo Boffi

Introduction

General Principles

Analysis of Beams

Bending Stresses

Lateral Buckling

Shear Stresses

Bearing Stresses

Torsion

Shear Center

Deflections

Principal Stresses

Design of Beams

For a rectangular section it is

$$J = \frac{bd^3}{12}, \quad \sigma_{\max} = \frac{Md/2}{bd^3/12} = \frac{M}{bd^2/6} = M/W$$

where  $W = bd^2/6$  is the *section modulus*.

It is clear that if the double the amount of material in a beam by doubling the width  $b$  the maximum stress is halved, if we double the depth  $d$  the stress is reduced to one quarter.

### Example

Simply supported beam,  $L = 7.2$  m,  $P = 20$  kN applied at midspan,  
 $M_{\max} = PL/4 = 36$  kN m = 36 MN mm.

Rectangular section,  $b = 120$  mm and  $d = 200$  mm,  $J = 80 \times 10^6$  mm<sup>4</sup> and  
 $W = 800 \times 10^3$  mm<sup>3</sup>, eventually  $\sigma_{\max} = 45$  MPa.

Principal Stresses

Design of Beams

To find the position of the neutral axis

1. draw an axis parallel to the neutral one at a(n unknown) distance  $y_G$  from it,
2. the distance from the neutral axis, in terms of the distance of the temporary axis, is  $y - y_G$ ,
3. the stress is  $\sigma = (y - y_G)k$ ,
4. the stress resultant is  $N = \int_A \sigma dA = k \int_A (y - y_G) dA = k \int_A y dA - ky_G A$
5. we have  $N = 0$  hence

$$y_G = \frac{S_x}{A} \text{ where } S_x = \int_A y dA$$

Similarly  $x_G = S_y/A$  with  $S_y = \int_A x dA$ .

We have found the position of the *centroid* of the cross section w/r to two arbitrary axes.

Principal Stresses

Design of Beams

The moment of the stresses about the neutral axes, if now we measure the distances from it, is  $M = \int_A y \sigma dA = k \int_A y^2 dA = k J_x$  by the definition of moment of inertia, so that we can solve for  $k = M/J_x$  and eventually we can write

$$\sigma = \frac{M}{J_x} y.$$

The expression above coincides with the expression that was shown earlier w/o an explanation.

Design of Beams

The moments of inertia of many simple figures are tabulated, with respect to their own centroids. We can use these known results along with *parallel axis theorem*.

### Theorem

The moment of inertia  $J$  of an area  $A$ , with respect to a axis parallel to an axis passing for its centroid is equal to the sum of the centroidal moment of inertia  $J'$  plus the moment of transport  $\Delta^2 A$

$$J = J' + \Delta^2 A$$

where  $\Delta$  is the distance between the two axes.

Design of Beams

- ▶ On the left, a “beam” composed of three equal, separate sheets, each one behaves the same,
- ▶ on the right, the sheets have been glued and the top sheet is shortened while the bottom one is elongated.

This behavior is possible only if the sheets exchange tangential stresses at their interfaces.

These tangential stresses are the shear stresses.

## Shear Stresses

Beams

Giacomo Boffi

Introduction

Principal Stresses

Design of Beams

E.g., for a rectangular beam the resultants of compressive and tensile stresses lie at  $d/6$  from the borders, so their arm is  $a = 2d/3$  and we have

$$T = C = M/a = 1.5M/d.$$

Consider now a slice of beam cut between  $x_1$  and  $x_2 = x_1 + \delta$  and separated in two halves at the neutral axis, the bottom part is subjected to two forces

$T_1 = 1.5M_1/d$  and  $T_2 = 1.5M_2/d$ , we have an unbalanced force

$$U = 1.5 \frac{M(x_1 + \delta) - M(x_1)}{d}.$$

For  $\delta \rightarrow dx$  it is

$$dU = 1.5dM/d = 1.5V dx/d,$$

the area available for equilibrating the unbalanced force using tangential stresses is  $dA = b dx$  so eventually

$$\tau = dU/dA = 1.5V/(bd).$$

Design of Beams

The procedure can be generalized, we know that  $\sigma = My/J$  so the resultant for an area  $A^*$  is

$$F = \frac{M}{J} \int_{A^*} y dA = \frac{M}{J} S^*$$

where  $S^*$  is the first moment of the area  $A^*$  w/r to the neutral axis.

The variation of  $F$  over  $dx$ ,  $dF = S^* V dx/J$ , is the unbalanced force to equilibrate over an area  $dA = b dx$  so that

$$\tau = \frac{V S^*}{b J}.$$

Design of Beams

For the T section we have previously studied, consider a maximum shear  $V = 4800$  N and consider that the flange and the web have been glued together ( $b = 6$  mm).

We have to compute  $S^*$  for the flange

$$S^* = \int_{30}^{36} 30y dy = 5940 \text{ mm}^3$$

and compute  $\tau$

$$\tau = \frac{V S^*}{b J} = \frac{4800 \times 5940}{6 \times 43200} \text{ MPa} = 110 \text{ MPa}.$$

Your glue must resist to a tangential stress of 110MPa.

Principal Stresses

Design of Beams

Just a few formulas,  $E$  is the Young modulus of the material... for the cantilever, the concentrated load is at the free end, in the other cases the concentrated load is at midspan — the deflections are measured at the same points.

	Cantilever	Supported	Fixed Ends
$P$	$\frac{PL^3}{3EJ}$	$\frac{PL^3}{48EJ}$	$\frac{PL^3}{192EJ}$
$w$	$\frac{wL^4}{8EJ}$	$\frac{5wL^4}{384EJ}$	$\frac{wL^4}{384EJ}$

Note how much the displacements depend on the beam span, note also that different end conditions influence very much the deflections.

## Deflections

A simply supported beam,  $L = 6\text{m}$ , has a live load  $w = 3\text{kN m}^{-1}$ . The section is rectangular,  $b = 0.2\text{m}$  and  $d = 0.4\text{m}$ , the Young modulus is  $E = 12\text{GPa}$ . Compute the midspan displacement.

$$\Delta \approx 4 \text{ mm}$$

## Steel Beams

The design of a steel beam in most cases coincides with choosing a section in a catalogue of commonly available steel members.

The section you are going to choose has to satisfy two essential requirements in terms of strength and deformability.

- Strength: the section must be strong enough to resist the maximum value of the bending moment,

$$f_y W \geq M_{\max} \rightarrow W \geq M_{\max} / f_y.$$

- Deformability: the maximum deflection must be less than a fraction of the beam span,  $\Delta \leq L/k$ .

The value of  $k$  depends on the load cases used to compute the deflection (live vs dead vs combination) and the function that the beam has to perform (support a roof, a floor, a wall, etc).

E.g., for a simply supported beam subjected to a distributed load, supporting a wall

$$\Delta = \frac{5wL^4}{384EJ} \leq \frac{L}{200} \rightarrow J \geq \frac{1000wL^3}{384EJ}.$$

## Steel beams, plastic behavior

Steel is an elastic-plastic material, if the strain exceeds a certain amount the normal stress remains constant,  $\sigma = f_y$ .

What happens when  $M = Wf_y$  and the load is increasing?

When the external bending moment increases, the outer fibres are further pulled-pushed and in a larger part of the section the stress is equal to  $f_y$  — the part of the section that is still elastic is, otoh, smaller and smaller and the elastic stiffness of the section is diminishing.

At some point, when in all the section  $\sigma = \pm f_y$  the elastic stiffness is equal to 0. In terms of strength we have reached the *plastic moment*, in terms of stiffness we have formed a *plastic hinge*.

### Beams

## Steel beams, plastic behavior

For a rectangular beam  $W = bd^2/6$  and  $M_y = f_y bd^2/6$  is the maximum elastic moment. When  $\sigma = \pm f_y$  we have  $T = C = f_y bd/2$  and their arm is  $a = d/2$ , hence  $M_p = f_y bd^2/4$  is the moment of plasticization, that turns the section into a plastic hinge.

For a rectangular section  $M_p/M_y = 1.5$ , for different shapes we have different ratios.

For common I shaped sections, the ratio has an average value around 1.12, for a circular bar it's about 1.7 and it's 2.0 for a diamond shaped bar.

## RC Principles

Concrete resists very well compression, resists very poorly tension.  
A plain concrete beam when loaded will tend to crack vertically in zones of (relatively) large bending moments and diagonally in zones of high shear and eventually break down for small loadings.  
To avoid the crack growth and the eventual failure we dispose some tension resistant material perpendicular to the cracks' directions, usually steel bars, longitudinal steel bars to equilibrate bending moments and vertical stirrups (U-shaped bars) or diagonally bent bars to equilibrate shear forces.

[Analysis of Beams](#)

[Design of Beams](#)

[General Principles](#)

[Timber](#)

[Steel](#)

[Reinforced Concrete: Principles](#)

[Reinforced Concrete: Procedures](#)

## Principles of reinforcement design

Design of reinforcement, especially the longitudinal reinforcement, is a balancing act.

If you provide not enough steel, the section will collapse by breakage of the reinforcement, but also providing too much steel leads to a bad design in which the failure of the beam happens when the compressed concrete is crushed.  
Concrete has a degree of ductility when compressed, but when its deformation is excessive it breaks suddenly.

A RC beam correctly designed has the right amount of reinforcement, so that the first yielding happens in the steel and we reach a limit state in which most of the concrete is safely plasticized and the steel deformations are still under control.

In this case a possible failure of a beam is preceded by a visual increase of deflections. Further, the possibility of a plastic behavior leads to an energy dissipation that is useful to control the response to seismic excitation.

## RC design at the limit state

To have a correct ductility, a good design choice is to assign appropriate values to the steel and concrete deformations.

Min Overall Depth (U.S. practice)

Member	Simply Supported	H+F	F+F	Cantilever
Slabs	$L/20$	$L/24$	$L/28$	$L/10$
Beams	$L/16$	$L/18$	$L/21$	$L/8$

Overall depth  $h$  is the reinforcement depth  $d$  plus the bottom concrete cover.
