The equation of stability 2n = r + b means also that the number of unknowns (r + b) must be equal to the number of independent equations that we can write (2n).

Drawing the diagrams of shear and moment for the truss considered as a beam gives you an insight on the forces that are requested in members and the required strength.

We have more unknowns (forces) than equations to determine them.

We can choose arbitrarily r + b - 2n values for the forces and determine the other forces using the remaining equations.

Is this possible?

NO, because the additional restraints means that not every deformation is possible.

We have to choose the *hyperstatic* forces so that the additional conditions on deformations are respected.

Spatial Trusses

The basic block is based on triangles and it is the *tetrahedron*.

For joints, we have to write 3 equations of equilibrium, hence a statically determined system must satisfy the condition

$$r+b=3n$$
.

For a section, we have at our disposal 6 equations of equilibrium.

In many cases the chords can be made using a continuous piece of material (a steel beam, a wood member, etc) and it is unappropriate to section it so that we can connect the parts using a pinned connection.

This implies that the joint can develop a bending moment — these bending moments are usually small w/r to the bending moment resistance of members designed to resist the axial loads and can be disregarded in a preliminary design.

Funicularly shaped trusses: depths vary with bending moment (horizontal components of chord forces are equal and diagonals are zero-force members under design loadings). Shaped trusses with no diagonals are built with rigid joints to handle varying loadings (see Chapter 9 on rigid-frame structures).

are very common, they are typically designed as beams with continuous chords designed to resist the maximum moment.

Different diagonal configurations can be chosen, taking into consideration the need for reducing the length of compressed members, subjected to lateral instability.

Configuration

Funicularly Shaped Trusses have s varying depth, chosen so that the loaded chord act as an arch and all the diagonal elements act only in terms of stiffening the compressed members and giving resistance to loads different from the loads that lead to design.

in general you can say that deep trusses, deep w/r to their span, are more efficient than relatively shallow ones.

- ▶ lightly loaded, closely spaced trusses $d/L \approx 1/20$
- ▶ trusses carrying secondary beams $d/L \approx 1/10$
- **ightharpoonup** trusses carrying e.g., columns near the ground level $d/L \approx 1/4$ or the maximum permitted by the storey height.

Different loading conditions (e.g., snow vs wind) determine *very different* actions in the members of the truss.

Our task is to identify, for each member, the critical loading.
